

Critical Fourier control and the scalar-charge obstruction

scaling exponent $\sigma + 1$

Bridge decision: scalar degree majorant = finite | nontrivial scalar charge = impossible under additivity + rotation | shell-angle-polarization state = open

Critical bound: $\|\mathcal{T}(u, v)\|_{\varepsilon'} \leq \nu^{-1} \|u\|_{\varepsilon} \|v\|_{\varepsilon}$. The exact high-high-to-low family shows that scale separation supplies no extra small factor.

Charge no-go: $\chi(\xi + \eta) = \chi(\xi) + \chi(\eta)$ and $\chi(R\xi) = \chi(\xi)$ for every $R \in SO(3)$ imply $\chi \equiv 0$.

Scope: classical critical small-data baseline plus one direct-interface obstruction · 17/17 checks · no three-dimensional Navier-Stokes regularity claim
